Plan Bouquet based Techniques for Variable Sized Databases

M.Tech Project Report (CSA)

Achint Chaudhary

April 13th, 2020

ABSTRACT

OLAP applications often require a certain set of canned queries to be fired on database with varying the constants in query templates. For optimal execution of these queries, query optimizer does select a strategy known as the query execution plan. These choices are based on cardinality estimates of various predicates that often hugely differ from actual cardinality values encountered during execution. Due to this reason, optimizer choice leads to high inflation in actual execution cost as compared to predicted cost during optimization.

An altogether different approach for query processing was proposed in 2014, named Plan Bouquet [1]. Basis of which is selectivity discovery at run-time by repeated cost bounded execution of carefully chosen to set of plans. This technique provides strong bounds independent of data distribution.

However, Plan Bouquet on cost sub-optimality is not designed to be robust against large updates in the database. This work focuses on observing limits up to which size of database can be increased without serious deterioration in performance guarantee. Also, we will provide incremental algorithms that can use information from plan bouquet compiled in past and extend it, to provide further robust execution without incurring overhead of re-compiling entire plan bouquet.

1 INTRODUCTION

Database query optimizer chooses a plan comprising of various structural choices of logical and physical operators for query execution. These choices are based on the cost of each operator which is calculated using number of tuples it will process known as $cardinality$. Cardinality normalized in range of $[0, 1]$ is known as $selectivity$ throughout literature.

These selectivity values are estimated before query execution based on some statistical models used in classical cost-based optimizers. An entirely different approach based on run-time selectivity

discovery is proposed called Plan Bouquet, which provides for the first time strong theoretical bounds on worst-case performance as compared to oracular optimal performance possible from all the available plan choices.

For each given query, predicates prone to selectivity error contribute as dimension in $Error-prone\ Selectivity\ Space\ (ESS)$ ESS is a multi-dimensional hypercube. The set of optimal plans over the entire range of selectivity values in ESS is called $Paramteric\ Optimal\ Set\ of\ Plans (POSP)$. POSP is generated by asking optimizer's chosen plans at various selectivity locations in ESS using selectivity injection module. Cost surface generated over entire ESS is called $Optimal\ Cost\ Surface (OCS)$. An $Iso-cost\ Surface\ (IC)$ is collection of all points from OCS which have same cost of optimal plan at each of these locations cost.

A subset of POSP is identified as $Plan\ Bouquet$, which is obtained by the intersection of plan trajectories with OCS, creating multiple Iso-cost surfaces, each of which is placed at some cost-ratio (r_{pb}) from the previous surface. Following Fig 1. depicts and exemplar OCS and its intersection with IC trajectories for a sample 2-Dimensional ESS.

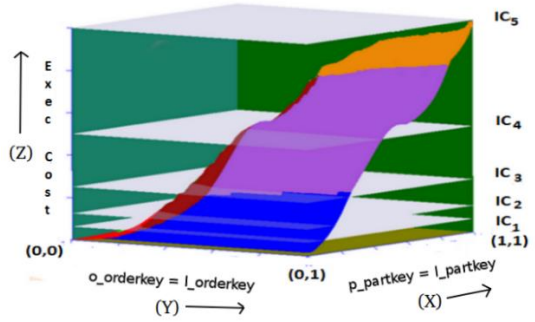

Fig 1. OCS and Plan Trajectories intersection

Since each plan on an iso-cost surface has a bounded execution limit, and incurred cost by execution using bouquet will form geometric progression. The figure below shows the performance of 1D plan bouquet w.r.t to optimal oracular performance.

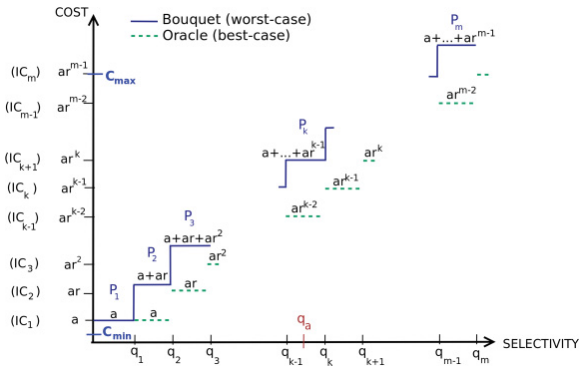

Fig 2. Cost incurred (Oracular vs Bouquet)

In above figure, various plans up to actual selectivity value q_a are executed. Each plan has a limit provided by the next iso-cost surface. This yields total execution cost of

$$C_{bouquet}(q_a) = cost(IC_1) + cost(IC_2) + \cdots + cost(IC_k)$$

$$= a + ar_{pb} + ar_{pb}^2 + \cdots + ar_{pb}^{k-1}$$

$$= \frac{a(r_{pb}^k - 1)}{r_{pb} - 1}$$

This leads to Sub-Optimality (ratio of incurred cost to optimal cost) of bouquet approach as

$$SubOpt(*, q_a) \leq \frac{\frac{a(r_{pb}^k - 1)}{r_{pb} - 1}}{a r_{pb}^{k-2}}$$
$$= \frac{r_{pb}^2}{r_{pb} - 1} - \frac{r_{pb}^{2-k}}{r_{pb} - 1}$$
$$\leq \frac{r_{pb}^2}{r_{pb} - 1}$$

This value is minimized using $r_{pb} = 2$, which provides theoretical worst case bound of 4 times the optimal execution time.

Extending the same idea to multiple dimensional ESS, MSO guarantee will become $4 * \rho$, where ρ is maximum cardinality (of plans) on any of iso-cost surface.

Since computing value of ρ will need huge compile time effort, it is platform dependent and desired low value of ρ is obtained using anorexic reduction heuristic at the time, plan bouquet was developed.

Later an improved algorithm called $Spillbound$ [2] is invented, which is able to provide performance guarantee based only on query inspection and is quadratic function in number of error-prone predicates, which is same as dimensionality of ESS. MSO guarantee obtained by SpillBound is

$$D^2 + 3D$$

We will be using SpillBound in some sections for our work, as it provides pre-compilation performance guarantee based just on query inspection, and also platform independent

2. PROBLEM FORMULATION

2.a Notations

Notation	Description
SP	Selectivity Predicates
WKP	Well Known Predicates
EPP	Error Prone Predicates
TP	Trivial Predicates
ESS	EPP Selectivity Space
OCS	Optimal Cost Surface
$POSP$	Parametric Optimal Set of Plans
RES	Resolution of Discretized ESS
Dim	Dimension of ESS
$(1+\Delta)_i$ or S_i	Scaling Factor of Predicate SP_i
$\mathcal{E}_i$	Minimum Selectivity on Predicate SP_i
m	Number of Iso-cost Contours
IC_i	Iso-cost contour with index i
CC_i	Cost Budget of IC_i
r_{pb}	Cost Ratio of Iso-cost contours
$(0, 1.0]$ or $[\mathcal{E}, 1.0]$	Selectivity interval for an axis of Discretized ESS
P_j	Plan with assigned identity j
F_i	Plan Cost Function for Plan P_i
$Cost(P, q)$	Cost of plan P at location q in ESS of reference database

$Card(p, q, scale)$	Cardinality of predicate p at location which has undergone change of $scale$ w.r.t to reference database
d_{sel}	Difference in consecutive selectivity values on axis of ESS
r_{sel}	Ratio of consecutive selectivity values on axis of ESS
β_{max}	Worst case slope of Plan Cost Function
α	Tolerance of contour thickening

2.b Assumptions

2.b.1 Plan Cost Monotonicity (PCM)

This assumption implies that if location q_j spatially dominates location q_i in ESS, Cost of optimal plan at location q_j is more than cost of optimal plan at location q_i.

$$(q_j \succ q_i) \rightarrow (Cost(q_j) > Cost(q_i))$$

This also comes from a simple fact that processing more tuples will incur more cost.

Also, we assume that Plan Cost functions & OCS are continuous & smooth in nature

2.b.2 Axis Parallel Concavity (APC)

This assumption as stated in [3] is on Plan Cost Function (PCF_p) which is not just monotonic but exhibit a weak form of $concavity$ in their cost trajectories. For 1D ESS, PCF_p is said to be concave if for any two selectivities locations q_a, q_b from ESS and any $\theta \in [0,1]$ following condition holds

$$F_p(\theta * q_a + (1-\theta) * q_b) \geq \theta * F(q_a) + (1-\theta) * F(q_b)$$

Generalizing to D dimensions, a PCF F_p is said to be $axis\ parallel\ concave\ (APC)$ if the function is concave along every axis-parallel 1D segment of ESS.

Which simply states that each PCF should be concave along every vertical and horizontal line in the ESS

Further, an important and easily provable implication of the $PCFs$ exhibiting APC is that the corresponding $Optimal\ Cost\ Surface\ (OCS)$, which is the infimum of the PCFs, also satisfies APC. Finally, for ease of presentation, we will generically use concavity to mean APC in the remainder of this work.

2.b.3 Bounded Cost Growth (BCG)

BCG property as defined by [4], is as follows for Plan cost function a F_p

$$F_p(\alpha * q.j) \leq f(\alpha) * F(q.j)$$

$$\forall j \in \{1,2,\dots,D\}\ and\ \forall \alpha \geq 1$$

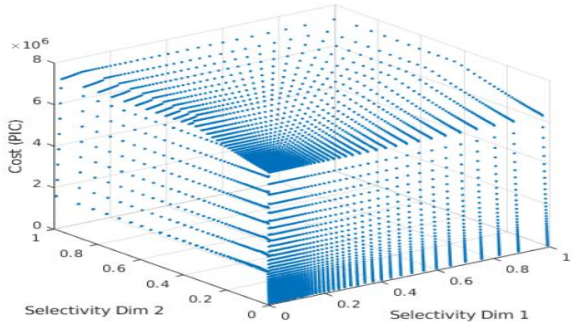
Here $f(\alpha)$ is an increasing function. Increase in selectivity by $\alpha \geq 1$ will result in maximum cost increase by factor of $f(\alpha)$.

Like APC, BCG if holds for all PCF also holds for OCS.

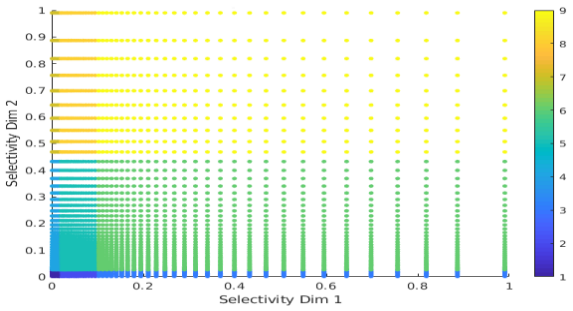
They have also claimed that identity function $f(\alpha) = \alpha$ suffice in practice.

2.b.4 Piecewise Axis Parallel Linear (APL)

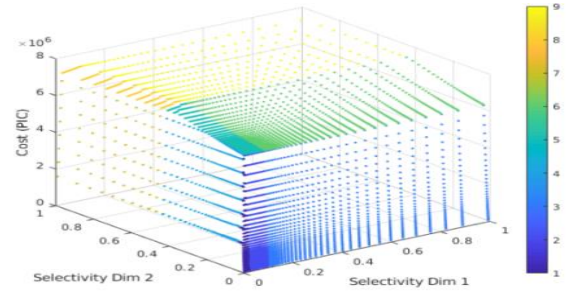
Plan Cost functions & OCS are shown to be piecewise linear in [5]. This property commonly comes from the fact that partial derivatives of common physical operators (except the sort operator, which is seldom found in industry strength benchmark [4]) are linear in nature.



(a) Original OCS



(b) Partitioned OCS Domain



(c) OCS fitted with Piecewise functions

Fig 3. Multiple APL functions to fit OCS

When it is the case that OCS or Plan cost functions are not truly piecewise linear, a coarse approximation of piecewise linear function can still be fitted to them. Similar work is done in our lab also in past by [6].

While in our work, we don't explicitly need to fit any such piecewise linear function. This will reduce our effort of fitting points from entire OCS into a piecewise APL function which will itself be exponential in nature.

2.b.5 EPP are the only predicates

For present analysis, we have considered that all of query predicates are Error-prone, there is also no trivial predicate, which means each relation has some filter predicate applied over it, which will be also considered as error-prone in our conservative assumption.

$$EPP \leftarrow SP\ (i.e., WKP \cup EPP \cup TP)$$

Rational behind this assumption is that, if we supply same selectivity value to both old and new database, their outputs will be of different cardinalities. If we have not gone with this conservative assumption, we will need to determine change of scale for WKP and TP, and for now we wish to handle all kind of predicates in same picture of analysis.

2.b.6 Perfect Cost Model of Optimizer

This assumption states that poor choices of plan come only from cardinality estimation error of optimizer and not from cost model itself. While, we have assumed perfect cost model of optimizer, an optimizer with

bounded cost model will also work well. Improving, which is an orthogonal problem. One work on offline tuning [7], proves that cost model can be tuned to predict value within 30% of estimated cost values.

2.b.7 Selectivity Independence

We assume that selectivity of predicates is independent of each other, while this is a common assumption in query optimization literature, it often does not hold in practice.

2.c Performance Metrics

2.c.1 Sub-optimality

It is ratio of cost incurred due to wrong selectivity estimation, as compared to optimal cost possible when actual selectivity is known a prior to system

$$Subopt(q_e, q_a) = \frac{Cost\left(P_{opt}(q_e)\right)}{Cost\left(P_{opt}(q_a)\right)}$$

Here, $q_e, q_a \in ESS$

This definition can be extended to plan bouquet where multiple executions takes place in a sequence BS with their respective budgets. So, definition will be

$$Subopt(*, q_a) = \frac{\sum_{exec \in BS} Budget(exec)}{Cost\left(P_{opt}(q_a)\right)}$$

2.c.2 Worst case Sub-optimality

Worst case suboptimality is Sub-optimality w.r.t to q_{est} that causes maximum Sub-optimality. This is devised for classic optimizer-based model

$$Subopt_{worst}(q_a) = \max_{q_e \in ESS} Subopt(q_e, q_a)$$

2.c.3 Maximum Sub-optimality (MSO)

Global worst case is with all possible combinations of q_e and q_a over ESS, which is

$$MSO = \max_{q_a \in ESS} Subopt_{worst}(q_a)$$

MSO for a sequence of execution from bouquet will be

$$MSO = \max_{q_a \in ESS} Subopt(*, q_a)$$

Theoretical guarantee is denoted as MSO_g & empirical obtained is denoted as MSO_e

2.d Updated notion of Selectivity Intervals

Selectivity is the fraction of tuples out of maximum possible tuples, that can come out of a query predicate. Notation of selectivity is devised to make study of ESS independent of cardinality values. This has motivated in past literature that selectivity value be always bounded in range [0,1].

Now, we will look at type of changes in data stored in a database instance. It can be:

I. Distributional Change
II. Volumetric Change

Since plan bouquet and later devised techniques are robust to distributional changes. In the case when only data distribution has changed and all predicates are error-prone, a plan bouquet compiled in past can be re-used with same MSO_g.

While, in the case of increase in size of database, Number of tuples to process and maximum possible tuples for any predicate generally increase.

Also, optimizer's choice for physical operator is highly dependent on cardinality values, hence those choices and resulting plans are also amenable to change.

So, if we go with [0,1] picture of selectivity for both earlier & updated instance, same selectivity value will result in different cardinality on database before and after volumetric update.

This difference of cardinality for same selectivity value in both instances will led to change in choice of operators and may result into overall change in structure of plans. This will ultimately change both shape of iso-cost contours as well as plans lying on them.

When we are looking to use information from contours generated on earlier instance for incremental or faster compilation. This rigid picture of [0,1] selectivity will bring problem in easy analysis.

So, across multiple instances of database, same selectivity value should return a same cardinality across multiple instances.

In a loose sense, selectivity to cardinality mapping should not be changed across different sized instances, while we opt to change the selectivity interval for our analysis.

For example, if total tuples in a relation before update are 100, and post update it has become 200. Then, we wish that 0.5 selectivity on both databases should return 50 tuples (this 50 is with reference to earlier instance). So, for initial database selectivity values are from [0,1], while for instance post update, legal selectivity interval is [0,2].

Note that, only the base (reference) instance on which plan bouquet is first compiled has selectivity values in [0,1]

This may seem to be fuzzy at first, but we will later show importance of this notation for reducing cost of incremental compilation.

Also, we will look change in volume from ratio of change in maximum cardinality possible from a predicate. This comes from that notion that each axis of ESS denotes a predicate. Hence, ESS upon change in database may have grown differently on each axis of ESS.

A pictorial representation of this approach is shown. Also, potential regions for which Incremental algorithms are needed to be developed are mentioned in the Fig 4.

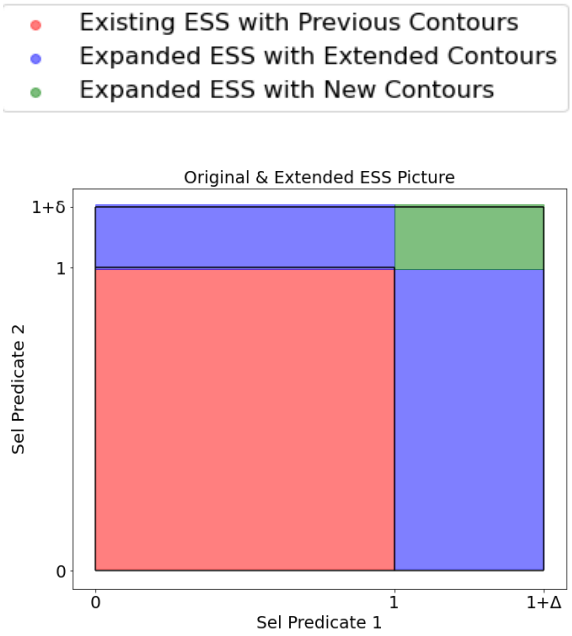


Fig 4. Representation of Different regions of concern in cardinality space, with new approach of selectivity intervals

In above diagram. Green region is the portion for which standard compilation procedure of contour discovery need to be called.

For now, we will look for approaches to

I. Extend existing contours which lie at intersection boundaries of red & blue regions into blue region. Note that if a contour will extend in both blue regions above, two seeds will be discovered and two independent NEXUS, one for each blue region will execute to extend each contour.

II. Check impact of update in cost of points lying on contours with information of their location in ESS and optimal plan at each individual point. This calculation will be helpful to provide relaxed MSO_g from using old contours and plans within red region

III. Incrementally compile contours in red regions. If usage of any old contour is deteriorating performance guarantee significantly.

During incremental compilation, information from past contours can be used to speed up contour discovery.

3 CHALLENGES W.R.T UPDATES

Under situation of change in database instance, placements of ideal contours can be totally different from existing contours built from earlier database instance, which may result that old bouquet contours and plans on them are totally different from new bouquet contours. Under above mentioned conditions it seems that a re-compilation will be needed.

Plan bouquet is suitable for canned queries as compilation overhead of entire discretized ESS enumeration will take $O(RES^{Dim})$ cost, which is amortized over repeated invocations for canned queries.

Now we will look at how compilation (iso-cost surface identification) in past literature is done [1], and why under all present options compilation at it first place is resource exhaustive.

3.a Math behind compilation

$Origin$ & $Terminus$ are the extreme ends of ESS, with having minimum possible and maximum possible selectivity of each error-prone predicate respectively. Cost of optimal cost at both these points obtained via Selectivity Injection are denoted as C_{min} and C_{max} respectively. using these two values, number of iso-cost contours (m) is obtained as follows.

$$m = \left\lceil \log_{r_{pb}}\left(\frac{C_{max}}{C_{min}}\right) \right\rceil + 1$$

These m Iso-cost contours are drawn at r_{pb} cost ratio successively from C_{min} which is referenced as a , as first term of cost geometric progression. Last contour IC_m may be at ratio less than r_{pb} from IC_{m-1}.

Let's have a proof by cases that this will not impact MSO_g.

Case 1: Actual selectivity is discoverable up to execution of plan from IC_{m-1} or any contour before than that, let that contour be IC_i. In that case for 1D Plan bouquet

$$\begin{aligned} &SubOpt(*, q_a) \\ &= \frac{ar_{pb}^{i-1} + ar_{pb}^{i-2} + \cdots + ar_{pb}^{1} + ar_{pb}^{0}}{ar_{pb}^{i-2}} \\ &\leq \frac{\frac{a\left(r_{pb}^{i} - 1\right)}{r_{pb} - 1}}{ar_{pb}^{i-2}} \\ &= \frac{r_{pb}^{2}}{r_{pb} - 1} - \frac{r_{pb}^{2-i}}{r_{pb} - 1} \\ &\leq \frac{r_{pb}^{2}}{r_{pb} - 1} \end{aligned}$$

Case 2: Actual selectivity is discovered on execution of plan from IC_m. In that case

Let this ratio of IC_m from IC_{m-1} be r_{last}. Also, $r_{last} < r_{pb}$. Now using expression for sum of geometric progression, which is used evaluate $MSOg$ for plan bouquet is

$$\begin{aligned} &SubOpt(*, q_a) \\ &\leq \frac{ar_{pb}^{m-2} r_{last} + \frac{a\left(r_{pb}^{m-1} - 1\right)}{r_{pb} - 1}}{ar_{pb}^{m-2}} \\ &= r_{last} + \frac{r_{pb}}{r_{pb} - 1} - \frac{r_{pb}^{2-m}}{r_{pb} - 1} \\ &\leq r_{last} + \frac{r_{pb}}{r_{pb} - 1} \end{aligned}$$

To maximize this upper bound, we substitute upper bound of r_{last} which is r_{pb}. Hence, resulting expression will be

$$\begin{aligned} r_{last} + \frac{r_{pb}}{r_{pb} - 1} &\leq r_{pb} + \frac{r_{pb}}{r_{pb} - 1} \\ &= \frac{r_{pb}^{2}}{r_{pb} - 1} \end{aligned}$$

In both Case 1. and Case 2. We have got same final expression, while in case 2. We have used upper bound for r_{last}. This mean expression from Case 1 provides MSO_g.

When $r_{pb} = 2$ is substituted in final expression, sub-optimality in that case is also upper bounded by 4.

This same proof can be easily extended for multi-dimensional plan bouquet.

Hence, we can state that last contour can be placed at lesser than r_{pb} cost ratio yet will provide same MSO_g.

3.b Compilation Methods & Overheads

Next step of compilation is to identify selectivity location and their optimal plans for each of iso-cost contours.

For now, there are two options available for contour construction:

I. Full ESS enumeration
II. NEXUS.

Let's see them one by one

3.b.1 Full discretized ESS Enumeration

This is most naïve yet effective approach and will be referred as full space enumeration at most places. In this approach optimal plan and its cost at all points of ESS is asked from query optimizer.

Points at which optimal plan's cost is equal to cost value of any iso-cost contour is qualified to be added to that contour. This will incur $O(RES^{Dim})$ optimizer calls. Where RES is resolution chosen to discretize ESS, while Dim is dimension of ESS. Each dimension in ESS represents a error-prone predicate.

This approach is certainly Exponential in number of dimensions, and a suitable value of RES should be chosen to make overall cost computationally feasible. Full space enumeration can completely exploit parallel architecture of modem multi-core systems available.

3.b.2 NEXUS (NEighborhood Exploration Using Seed)

An optimization over full space enumeration is introduced with plan bouquet [1]. NEXUS is an algorithm proposed to avoid making unnecessary optimizer calls on points lying in between contours. If we have total m iso-cost contours to discover, worst case complexity of NEXUS for entire compilation process can go up to $O(m * D * RES^{Dim-1})$

At first NEXUS seems to be promising for reducing compilation overhead, but faces multiple following issues [8]:

I. If large number of contours needs to be drawn, NEXUS is effectively close to Full space enumeration, especially in high dimensional ESS.
II. If a lower bound is known on query predicate's selectivity through domain knowledge, SpillBound can shrink ESS by making this lower bound as origin. However, NEXUS needs to redraw new iso-contours from scratch
III. Randomized contour placement to introduce fairness in Plan bouquet needs more contour need to be drawn. This makes NEXUS cumulatively more expensive than full space enumeration

NEXUS is worst case makes total optimizer calls twice the number of points lying on iso-cost contours.

Note: Both above methods of finding iso-cost contours make a common assumption that, Resolution of discretized ESS grid should be sufficiently high such that we can always find contiguous iso-cost locations with cost of optimal plans at these locations lying in interval $[CC_i, (1+\alpha)CC_i]$ even with small values of α, say, 0.05.

Due to this assumption, we will see some issues which are common to both Full ESS enumeration and NEXUS.

3.c Complexity Issues in compilation

Both methods have a common property with them:

I. Complexity exponential in Dim
II. Need of sufficiently high resolution on each axis

While an algorithm with complexity $O(RES^{Dim})$ becomes computationally unfeasible to run with sufficiently high-resolution dimensions of ESS.

To prevent this in practice, instead of going with sufficiently high resolution with uniform distribution of selectivity values on each axis. Experiments can be tried to run on low-resolution picture.

Next we will see a potential issue which may arise with use of low resolution with uniformly distributed selectivity values.

But first, we will discuss both methods in brief for a 2D ESS example, to find points lying on contour IC_i with cost CC_i

I. Full space enumeration

Points lying from grid in cost interval should be on contour if cost of optimal plan lies within cost interval $[\, CC_i \;,\; (1+\alpha)CC_i \,]$

II. NEXUS

Locate seed $S(x,y)$, then iterate to find next neighbor until loop ends to find any next location with given search condition.

$$while\ (S\ has\ a\ neighbor\ in\ 4^{th}\ quadrant):$$

$$if\ Cost\big(S(x,y-1)\big) < CC_i:$$

$$S(x,y) = S(x+1,y)$$

$$else:$$

$$S(x,y) = S(x,y-1)$$

Due to usage of low resolution, with low tolerance factor α. Full Space enumeration may result into incomplete contour, while NEXUS may result into contour will cost inflated more than factor of $(1+\alpha)$. Pictorial representation of potential issues encountered are depicted in Fig 5.

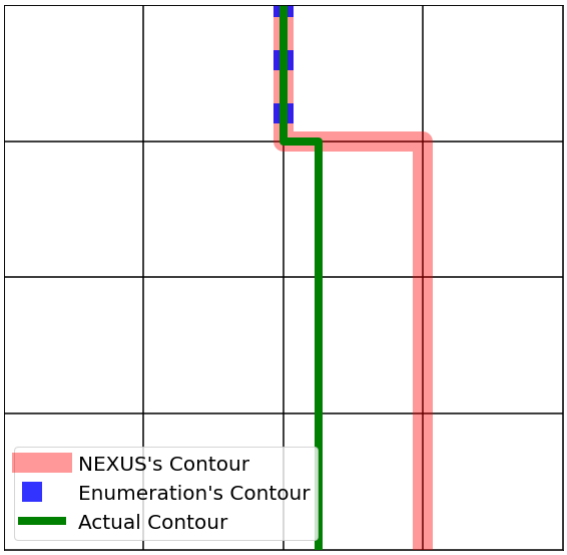

Fig 5. Contour discovery with low resolution and uniform selectivity distribution

To avoid this yet keeping computational feasibility, one possible option is to raise value of α. But that does impact MSO_g. Also, from observation and from APC, we know most changes in slope will happen close to origin.

So, to (empirically) avoid above explained issue, when working with low resolution and high dimensional ESS and to keep cost computationally feasible, geometric distribution of selectivity value was used on each axis of ESS in practice.

This use of low resolution and geometric distribution is never explicitly stated in literature and may violate MSO_g in practice.

This violation is not observed till yet, but proof for the same is also pending like a $conjecture$. Rational till now for use of Geometric distribution in selectivity space is that it captures many points in low selectivity values, and most changes in plan choices takes place in low selectivity values.

For making a geometric distribution to work, there are numerous hyper-parameters to tune. While methods, tips and techniques along with their impact on MSO_g are the missing part from literature which we will try to provide and prove in a systematic way.

4. CONTRIBUTIONS

4.a Increasing compilation efficiency

Few comments on NEXUS as discussed in [8] highlights some issues faced due to use of NEXUS. Two such major issues are:

(i) Same effective cost as full ESS enumeration

(ii) Need to redraw contours from scratch if lower bound on any selectivity predicate is known.

Fraction of speed-up of NEXUS over Full space enumeration is

$$O(\frac{RES}{m * D})$$

As number of dimensions D and number of contours to draw m increases, both are cases with queries with a greater number of EPP. Also, to make things feasible we choose low values of RES. All this aspect of moving towards tractable compilation time brings NEXUS close to Full space enumeration.

We will propose an upgrade in NEXUS to make it much faster than its competitor naïve algorithm.

But before we start working on a improved version of NEXUS, we will first try to look at second argument made against NEXUS

4.a.1 Impact of known lower bound

Consider a 1d example of plan bouquet. If lower bound on predicate selectivity known a prior is δ. Then selectivity interval will reduce from $[0\ ,1]$ to $[\delta\ ,1]$.

Let selectivity locations for each of contour IC_i be q_i. So,

$$IC = \{IC_1, IC_2, \dots, IC_m\}$$

$$Q = \{q_1, q_2, \dots, q_m\}$$

Here, $q_1 = 0\ and\ q_m = 1$

Let, δ lie beyond q_k, and actual selectivity q_a be discover upon execution of IC_i

So, contours IC_1through IC_k are no longer needed. Expression for suboptimality will be changed from

$$SubOpt(*, q_a)$$

$$= \frac{ar_{pb}^{i-1} + ar_{pb}^{i-2} + \cdots + ar_{pb}^{1} + ar_{pb}^{0}}{ar_{pb}^{i-2}}$$

To

$$SubOpt(*, q_a)$$

$$= \frac{ar_{pb}^{i-1} + ar_{pb}^{i-2} + \cdots + ar_{pb}^{1} + ar_{pb}^{k-1}}{ar_{pb}^{i-2}}$$

$$= \frac{\left(r_{pb}^{i} - r^{k-1}{}_{pb}\right)}{(r_{pb} - 1) r_{pb}^{i-2}}$$

$$\leq \frac{r_{pb}^{2}}{(r_{pb}^{2} - 1)}$$

This is same expression for MSO_g as seen in earlier contours. So, we can now state that with knowledge of lower bound of a predicate's selectivity, we can discard contours with points having selectivity of that predicate less than known lower bound. And still can achieve same MSO_g

Hence, now we are clear that knowledge of lower bound neither impact NEXUS nor Full space enumeration, contours drawn in past can be continued to use with any change in knowledge from lower bound.

We will revisit NEXUS and see scope of improvement based on some geometric properties and try to put on improvement into existing NEXUS algorithm.

Base idea of NEXUS is first locating a seed, which is one end point of contour; Use this seed to discover adjacent points of contour lying in 4th quadrant in its neighborhood. Below example borrowed from [1] shows working of NEXUS in pictorial way in Fig 6.

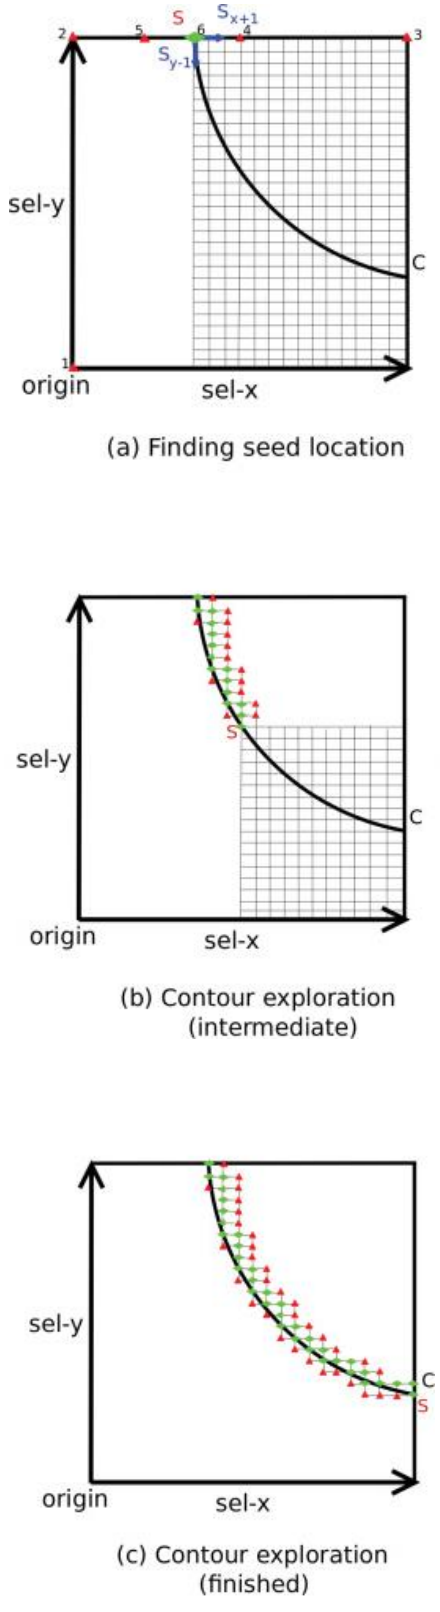

Fig 6. Working of NEXUS

NEXUS in worst case makes twice optimizer calls from number of points lying on contour in high resolution discretized ESS.

This at first glance looks bit smart, but we can still improve it using piecewise linear geometry of contours.

From past works [6, 10], contours are observed to be either piecewise linear or approximated to be piecewise linear. See figure for reference of contours generated on a 50GB TPC-DS with Query instance Q91.

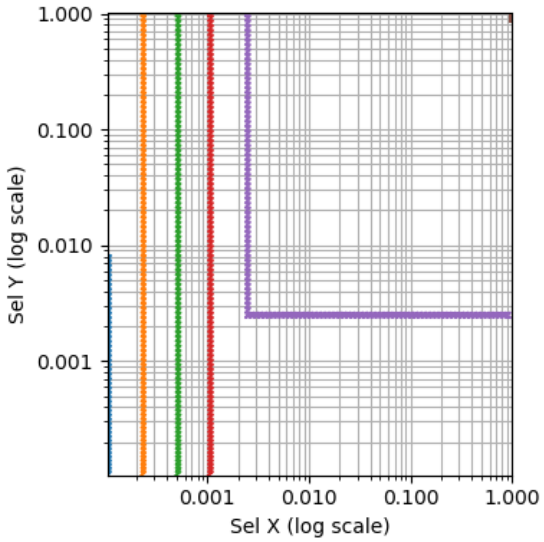

Fig 7. Q91 contours on 50GB TPC-DS

We'll attempt to utilize this highly piecewise linear nature of contours to get improved and faster version of NEXUS, namely NEXUS++, which should in practice speed up the contour discovery process, which is main cost overhead of compilation

We will use same seed discovery process as of NEXUS, using binary search in interval of valid axis, from where we can start the search. Next we'll look at design of contour exploration of NEXUS++

As an example, consider that red contour (which is 4th contour in the diagram). Seed as usual will be located on top boundary of ESS.

Now, what if we can magically get the slope of contour in ESS space (do not consider cost into picture), which is nothing but infinity, as contour is parallel to Y-axis.

We could have used $exponential\ search$ to reduce number of points on this where optimizer calls are made. In best case complexity will change from $O(RES)$ to $O(\log(RES))$.

There are some fundamental issues with this approach:

(i) Slope in ESS space for any piece of piecewise linear contour is not known a prior

(ii) Even if exact slope can be approximated somehow, Exponential search may miss some plans on contours due to large steps taken

First, we will see how to overcome the second issue in our idea.

We will be using bisection search to find if we can find a different plan in between two successive points discovered by Exponential search, and if a different plan is observed in either half, recursive function is called till any interval on bisection search has same plans on both end points, or interval length vanishes.

$\text{def } bisection(left, right):$

$P_L, P_R = P_{opt}(left), P_{opt}(right)$

$if\ (left \leq right)\ and\ (P_L\ != P_R):$

$mid = \frac{left+right}{2}$

$P_M = P_{opt}(mid)$

$if\ (P_L != P_M):$

$bisection(left,\ mid)$

$if\ (P_R != P_M):$

$bisection(mid,\ right)$

Algo 1. Bisection search to find plans missed by exponential search

Using above mentioned procedure within exponential search may yet not fully reduce optimizer call of find all plans in between. In case of large number of plans or alternating plans in between two points discovered by exponential search consecutively. First line in Fig 8 shows such a case, on base of which we will develop our concept further.

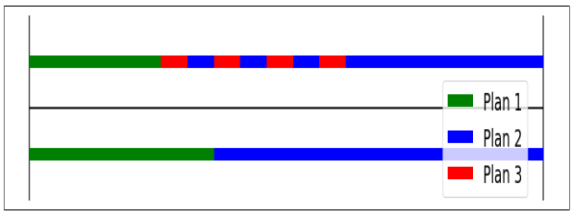

Fig 8. Alternating plans missed by bisection search

Plan bouquet relies on low contour density, which is obtained at Intra-contour level using Anorexic reduction, once we have obtained all points on Contour. While Spill bound doesn't rely on this reduction due to contour density independent execution.

We will be using a form of plan swallowing in bisection search. Which reduces the compilation efforts in terms of optimizer calls with expense of some FPC calls. This in practice reduces possibility of alternating with nearly same cost in region between two points discovered by exponential search. This will led to scenario as shown by second line in Fig 8.

We can modify our last procedure to implement cost swallowing to reduce overheads. Pseudo-code for which is as follows:

Let, λ be maximum cost relaxation due to plan swallowing, in practice 0.2 value is enough as done in literature [11]

$\psi = (1 + \lambda)$ // Plan substitution threshold

$\text{def } bisectionAPD(left, right):$

$P_L, P_R = P_{opt}(left), P_{opt}(right)$

$if\ (left \leq right)\ and\ (P_L\ != P_R):$

$mid = \frac{left+right}{2}$

$P_M = P_{opt}(mid)$

$if\ Cost(P_M, mid) * \psi \leq Cost(P_L, mid)$

$if\ (P_L != P_M):$

$bisection(left,\ mid)$

$if\ Cost(P_M, mid) * \psi \leq Cost(P_R, mid)$

$if\ (P_M != P_R):$

$bisection(mid,\ right)$

Algo 2. Bisection search with plan swallowing

Now coming to the first issue of our search approach, which is getting slope of each piece of piecewise linear function. Let us pose it as an online control system problem with feedback and fallback strategies.

As we know even with original NEXUS and Full ESS exploration, a tolerance interval of $[\,CC_i\,, (1+\alpha) * CC_i\,]$ (with sufficient low value of α, say, 0.05) is used and points are chosen such that surface thickening is avoided, which is points must be chosen as close as possible to lower bound of search cost interval.

We will exploit similar idea to search within cost interval $[(1-\alpha) * CC_i, (1+\alpha) * CC_i]$, and our search method will try to pick point having optimal cost lying in mid of specified cost interval.

With the knowledge of seed, we will start from one end of contour (one of the many connected linear pieces) and will search in 4th quadrant. Slope information will be obtained on-the-fly and tuned based of deviation from mid-value of cost interval so that search will always lie within the given interval. When search goes beyond the tolerable cost interval, we always have a fallback to last valid point and start again with half the step size taken in last wrong decision.

This will not constitute as an exact exponential search procedure but is expected to run much faster than linear step sizes in earlier NEXUS which exploits very less information about geometry of contour.

Also, a common observation is that, sum of all slope changes of contour will be maximum of right angle. In worst case, which is also observed in 5th contour in Fig 7. Contour will take a sharp right angle turn anti-clockwise in 4th quadrant. No fallback in search can get us the correct direction.

Once we have detected that fallback strategy will not work, we will go with exponential rotation in 4th contour anti-clockwise to get next correct direction. This method of dynamic tuning of slope with exponential steps and finding points missed in between using bisection search will require lesser optimizer calls for piecewise linear contours, which are observed in practice.

def $NEXUS++(CC_i)$:

$S_{now},\ P_{now} = InitializeSeed(CC_i)$

$C_{now} = Cost(P_{opt}, S_{now})$

$step,\ \Delta_{now} = 1\,,\ [-1, 0]$

$while\ True$:

$S_{next} = S_{now} + step * \Delta_{now}$

$C_{next} = Cost(P_{opt}\,, S_{next})$

$if\ \max\left(\frac{C_{next}}{CC_i}\,, \frac{CC_i}{C_{next}}\right) \leq (1+\alpha)$:

$\Delta_{now} = TuneDir(S_{now}\,, S_{next})$

$bisectionAPD(S_{now}\,,\ S_{next})$

$S_{now}\,, step = S_{next}\,, 2 * step$

$else$:

$if\ step > 1$:

$step = step\ /\ 2$

$else$:

$\Delta_{now} = RotateDir(S_{now}\,, \Delta_{now})$

Algo 3. NEXUS++ with $bisectionAPD$, Direction tuning & angle correction

We have not mentioned an strict condition on searched points to lie exactly in between cost interval $[(1-\alpha)*CC_i,\ (1+\alpha)*CC_i]$ like what is there in NEXUS to avoid surface thickening.

We have utilized idea behind $Q-Error$ [12] function to make algorithm choose points close to mid value of tolerable cost interval. An online tuning algorithm like $PID\ control$ [13] can be used for tuning direction vector.

Note that, this slope information is crucial, as if for highly piecewise linear contours, having a prior knowledge of slope will dramatically reduce number of optimizer calls which will otherwise be made during tuning to obtain correct slope.

4.b Geometric progression to discretize each axis of ESS with bounded MSO_g

Uniform selectivity distribution with high resolution is what earlier Full space exploration and NEXUS needs in practice. But from past work on Concavity [3], we know that most of changes in cost value happen close to origin.

To capture this behavior of OCS, we can go with two following options:

(i) Sufficiently high resolution with uniform distribution on each axis

(ii) Selectivity values should be chosen carefully in geometric progression with bounded relaxation in MSO_g

While, for high dimensional queries, it is not possible to go with first choice of high resolution. In this sub-section we will work on usage of selectivity values on each axis as a geometric distribution, and relaxed MSO bounds by going with this choice.

Use of Geometric progression with bounded slope of OCS for any predicate SP_i will result in bounded but relaxed MSO_g. Now we will prove the same

Formula for last term of GP is

$$b = ar^{n-1}$$

Using same in our framework and let ε_i be the minimum selectivity to start with on axis corresponding to SP_i.

$$1 = \varepsilon_i * r_i^{RES_i-1}$$

From slope bounded cost growth, we know

$$r_{cost} \leq \beta_{max} * r_{sel}$$

Combining above two equations and re-arranging will yield

$$\varepsilon_i \geq \left(\frac{\beta_i}{r_{cost}}\right)^{RES_i-1}$$

All four variables in resulting inequality are hyper-parameters to deploy ESS construction in practice. Let's see impact of each of these variables with their meaning.

Variable	Interpretation
ε_i	First selectivity value to start forming GP
RES_i	Resolution of ESS along axis of SP_i
β_i	Maximum slope of OCS w.r.t SP_i
r_{cost}	Ratio of cost change upon each step on selectivity axis of ESS

We will soon see a approach to find ε_i and β_i. For now, if we have these two values and given $r_{cost}(> \beta_i)$. We can get value of RES_i to build a Geometric progression of selectivity value along axis of SP_i in ESS as

$$RES = \left\lceil \log_{(\frac{\beta_i}{r_{cost}})}(\varepsilon_i) \right\rceil + 1$$

With a bounded relaxation factor of η in MSO_g, and since we have total of D dimensions in ESS. We will use

$$r_{cost} = \sqrt[D]{\eta}$$

This is maximum cost jump on each axis with use of geometric progression. Like proof of Frugal-SpillBound [3]. We can prove that with use of Geometric progression to construct ESS, relaxed MSO_g using plan bouquet will be

$$4 * \rho * \eta$$

Or, in case of SpillBound will become

$$(D^2 + 3D) * \eta$$

Now we will investigate computation of ε_i and β_i.

Calculation of $\hat{\varepsilon}$ for each SP_i

Let $\hat{0}$ be D-dimensional vector containing absolute zero selectivity values for each predicate. Also let $\hat{\varepsilon}$ be the vector we are looking for to construct geometric progression of selectivity value along each axis of ESS.

We will choose $\hat{\varepsilon}$ by doing binary search along diagonal connecting $\hat{0}$ and $\hat{1}$; Such that

$$\frac{Cost(\hat{\varepsilon})}{Cost(\hat{0})} \leq MSO_g$$

Since MSO_g computation before compilation is possible in SpillBound. We will use SpillBound in all our experiments

$\hat{\varepsilon}$ is chosen to be new origin, and terminus will be $\hat{1}$ as always during compilation.

This method provides $\hat{\varepsilon}$ for forming geometric progression on each axis of ESS. And, it also provides MSO_g for queries lying in $[\hat{0}, \hat{\varepsilon})^D$.

Calculation of $\hat{\beta}$ for each SP_i

Then, $\hat{\beta}$ can be calculated in close neighborhood of $\hat{\varepsilon}$ by varying value of each SP_i one at a time. Due to concavity assumption, highest slope will lie at origin $\hat{\varepsilon}$.

Up to here we have suggested empirical & algorithmic suggestions for gaining speed up in the compilation process itself.

Now we will look specifically at techniques which can handle incremental database instances in Plan bouquet-based algorithms.

4.c Computation of Inflated MSO

4.c.1 Exact inflated MSO_e for updated ESS

At first, we will look at a simple procedure to compute nearly accurate value of empirical guarantee value (MSE_e), under assumption of perfect model

We can choose all points in ESS, and simulate our robust algorithms (under assumption of perfect cost mode, simulation will work and can be done in parallel), and can find out maximum relaxed MSO_e. Complexity for this procedure will be

$$O(\prod_{i=1}^{Dim} RES_i) = O(RES^{Dim})$$

4.c.1 Inflated MSO_g for updated ESS.

With use of NEXUS++ and ESS with geometric distribution of selectivity values on each axis, we will obtain contours with far a smaller number of points on each contour than what would be with classic NEXUS and uniform distribution of selectivity values on each axis with high resolution.

In the combined (existing and extended) regions of ESS after database scales up. We'll use these points with FPC module to obtain inflated MSO_g , if we will continue to use old contours and their plans in existing region of ESS. Note that in the extended ESS, we will always go with standard compilation.

Now, we will look at an algorithm for efficient computation of MSO_g. Consider each contour IC is collection of tuples (q, P) where q is location on contour and P is plan at that point available on IC contour.

$r_{max} = r_{min} = r_{pb}$

$for \quad ix \in [1, m-1]:$

$early, next = ix, ix + 1$

$$\text{early}_{\min} = \min_{(q,P) \in IC_{early}} (Cost(P,q))$$
$$\text{early}_{\max} = \max_{(q,P) \in IC_{early}} (Cost(P,q))$$

$$\text{next}_{\min} = \min_{(q,P) \in IC_{next}} (Cost(P,q))$$
$$\text{next}_{\max} = \max_{(q,P) \in IC_{next}} (Cost(P,q))$$

$$r_{inflation} = \left(\frac{next_{max}}{early_{min}}\right)$$

$$r_{suppression} = \left(\frac{next_{min}}{early_{max}}\right)$$

$if\ r_{inflation} > r_{max}:$

$$r_{max} = \left(\frac{next_{max}}{early_{min}}\right)$$

$if\ r_{supression} < r_{min}:$

$$r_{min} = \left(\frac{next_{min}}{early_{max}}\right)$$

$$MSO_g = \max\left(MSO(r_{max}), MSO(r_{min})\right)$$

Algo 4. Computation of Inflated MSO_g

This method of computation of MSO_g does not involve any simulation of Plan bouquet-based algorithm, and will only include FPC calls, equal to sum of number of points on all contours.

Also, the way we are looking to extend ESS upon volumetric updates and try to use fix set of contours. One thing to note is that C_{min} will remain same across different instances. While r_{sel} which is ratio of selectivity change may increase when moving across axis into extended region.

So, like the way we computed inflated MSO_g. We can compute order of contours to re-construct to lower down inflated MSO_g close to ideal value of $4 * \rho$ or with SpillBound more precisely to $D^2 + 3D$.

Following procedure will find out contour causing max inflation in MSO_g using greedy approach and should be re-built. This

contour will be built using incremental NEXUS++, resulting in lesser inflated MSO_g.

def $GCC(Contour\ List)$:

$IC_{redo}, r_{change} = None, 1$

$for\ \ IC_{ix} \in Contour\ List:$

$$CC_{\min} = \min_{(q,P)\in IC_{ix}} \left(Cost(P,q)\right)$$

$$CC_{\max} = \max_{(q,P)\in IC_{ix}} \left(Cost(P,q)\right)$$

$$r_{deviation} = max\left(\frac{CC_{max}}{CC_{ix}}, \frac{CC_{ix}}{CC_{min}}\right)$$

$if\ r_{deviation} > r_{change}:$

$IC_{redo} = IC_{ix}$

$r_{change} = r_{deviation}$

$return\ IC_{redo}$

Algo 5. Greedy Contour Construction (GCC)

4.d Incremental bouquet maintenance

Up to now we have added efficient methods for compilation, relaxed MSO_g computation and choice of contours to re-draw. While another issue that we have not discussed yet is as follows.

A database may get multiple volumetric updates over time, on each update we will extend existing contours and draw few new ones. And not on each next update we will go with re-compilation of entire bouquet.

For current update, some part of existing ESS from first compilation may led to serious deterioration in MSO_g while impact from rest of part can be tolerated. A sample instance of this is shown in following Fig 9.

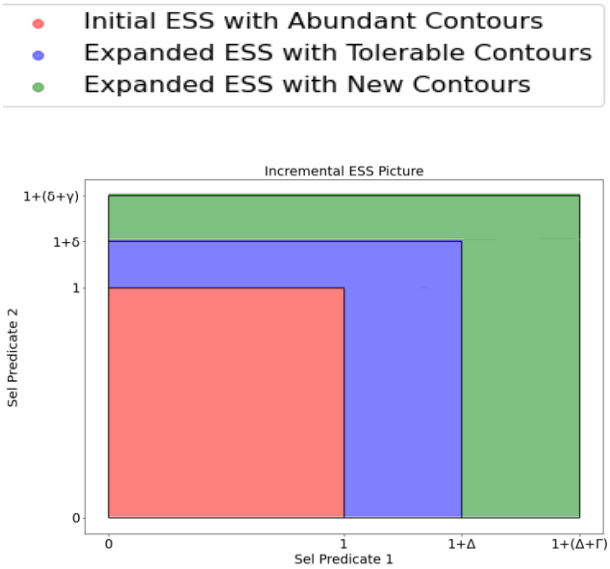

Fig 9. Possibility on variety of regions from extended ESS into constituting towards MSO_g upon successive updates

While contours lying in all these regions share same C_{min} and r_{pb}, hence cost values of contours can be exactly same between two regions of ESS (named sub-ESS). Contours lying in each region can be maintained independent of each other (for MSO_g impact & re-drawing using GCC Algorithm). Contours will same cost value lying in different sub-ESS need only be merged for execution of bouquet algorithm.

So, in above figure we can selectively re-draw contours in initial ESS shown in red color.

This approach enables us to avoid re-compilation on entire existing ESS, but only

bound to re-compile of sub-ESS impacting MSO_g. Also, it suggests that each sub-ESS should be maintained independent of each other

4.e Constant Selectivity to Cardinality mapping

We will now make another clear rationale to choose a selectivity notion not bounded within $[0, 1]$.

Cost based query optimizer chooses physical operators for each logical operator in abstract relational algebraic tree. Cost of multiple physical operators will be compared in two ways:

I. Absolute values
II. Relative values

Cost of operators used of base relation filter predicates are compared in a relative manner. While operators for Join are generally compared in absolute manner. Tipping point of these decisions are cardinality values where cost of both choice on either side is same.

To observe importance of this notion of selectivity interval outside $[0, 1]$ let's follow with an example.

Suppose, we have an SQL query with only single operator (corresponding to an EPP) where decision of choice of operator must be made. Let's make another assumption that this choice is based of absolute cost. Then form decision will be like:

$$if\ Cost(Operator_A) \leq Cost(Operator_A):$$

$$Use\ Operator_A\ in\ Query\ Plan$$

$$else:$$

$$Use\ Operator_B\ in\ Query\ Plan$$

Since, decision is absolute, tipping cardinality value will remain same not matter what maximum cardinality is possible for that selectivity predicate. Below Fig 10. pictorially represents the same

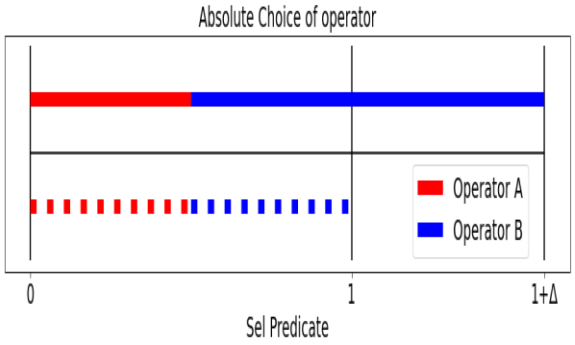

Fig 10. Dependency of absolute choice of operator on data volume to process

Dashed line shows the scale of data to process with different colors for each operator. Transition between two colors is the tipping point. Since decision is absolute, same cardinality value will remain tipping point even after database update. Which is shown as solid line for increased volume.

Suppose that for a SQL query, all predicates are error-prone (all data flowing into query execution plan has entered from some EPP), all choices are absolute, and optimizer has perfect cost model based on cardinalities only

Then choice of operator in [0, 1] interval will never change for each predicate. And since plan structure is just a arrangement of operator within tree, if cost of no operator is changing. Overall plans in ESS once compiled will remain same, leaving us only to compile contours in extended ESS. This is a picture which is too good to be true.

All choices are not absolute, most base relation filter predicates are relative in nature and tipping point of decision will change as depicted in figure below

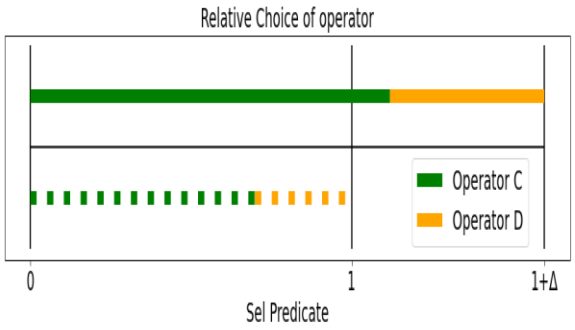

Fig 11. Dependency of relative choice of operator on data volume to process

$$if\ \frac{Cost(Operator_A)}{Cost(Operator_B)} \leq\ \delta :$$

$$Use\ Operator_A\ in\ Query\ Plan$$

$$else :$$

$$Use\ Operator_B\ in\ Query\ Plan$$

These relative choices will need one to re-compile (reconstruct contours) in some places within existing ESS also.

Now as we know that optimizer choices are perfectly cardinality based but can be both absolute and relative. Where relative choices in lower part of query plan may also affect absolute choices to be made in upper part of query plan, and vice versa.

We will exploit a basic idea, that tipping point for absolute choice-based operators will never change. Also, for operators having relative choice, tipping point between first two choices in decreasing order of their cost function complexity will always move to high cardinality value from last tipping point.

So, there will always be a region of ESS, where no operator decision will change ultimately leading to same optimal plan, no matter how much volumetric update will happen in database instance, we will call such region as $Safe - Sub - ESS$.

All contours lying completely in Safe-Sub-ESS will be called $Static\ contours$ and never need to be re-compiled or even checked during inflated MSO_g computation.

As point on those contours, their corresponding optimal plans and cost values will never change.

Also, will note that volume of Safe-Sub—ESS as compared to entire ESS depends on number of choices for implementing physical operators for each logical operator. While all platforms have variety of implementations, typical number for each logical operator still lies within 5.

4.f Finding *Static contours*

As we know all points on any contour IC_k will collectively dominates all contours from IC_1 to IC_{k-1}. So, contours should be attempted to marked static in increasing order of their cost budget.

A necessary condition for a contour to be static is that, it should lie completely within existing ESS. Also, cost of no point on static contour will change. This check using FPC will act as sufficient condition.

```
def CheckStatic(IC) :
    for (P, q) ∈ IC :
        if Cost_new(P, q) != Cost_old(P, q) :
            return False
    return True

def MarkStatic(DynamicContours) :
    for IC_i ∈ DynamicContours ;
        if IC_i.points ⊄ ExistingESS :
            break Loop
        bool_static = CheckStatic(IC_i)
        if bool_static :
            StaticContours.add( IC_i )
        else :
            break Loop
```

Algo 6. Pseudo-code for Marking static contours

4.g Using existing contour geometry

Even when we have better methods for drawing contours, most of cost involved in terms of optimizer calls are involved in tuning the slope value with exponential search.

In this section we will see an idea & corresponding algorithm that will pass some geometric information from existing contour which need to be re-drawn, into NEXUS++, so that lesser optimizer calls should results for tuning. While the idea is that if that geometric information is of no use for next contour, it will just result into more optimizer calls, as if NEXUS++ is working from scratch, without incurring any harm to MSO_g.

We will initialize two seeds, instead of one, and start search of our NEXUS++ from both these ends, taking one step at a time.

Slope information from both ends of previous contour is fed into NEXUS++. It will return two NEXUS++ instances, both of which will act as iterators, from which points will be drawn in interleaving fashion.

Among these two points, one initialized from starting seed will move forward, while another initialized from last seed value will move in reverse direction. While it must also be checked that point searched from end should always lie in 4th quadrant of point searched from beginning. If that condition is ever violated, a simple bisection search will work for all points between them.

$\text{def } BiNEXUS++(IC_i, CC_i):$

$S'_S, S'_L = Start(CC_i), Last(CC_i)$

$Iterator_s = NEXUS++(CC_i, IC_i, S'_S)$

$Iterator_L = NEXUS++(CC_i, IC_i, S'_L)$

$while\ |S'_S.x - S'_L.x| \wedge |S'_S.y - S'_L.y|:$

$step_S = Iterator_S.next()$

$if\ S'_S + step_s \leq S'_L:$

$S'_S = S'_S + step_s$

$else:$

$break\ Loop$

$step_L = Iterator_L.next()$

$if\ S'_S \leq S'_L - step_L:$

$S'_L = S'_L - step_s$

$else:$

$break\ Loop$

$if\ |S'_S.x - S'_L.x| \vee |S'_S.y - S'_L.y|:$

$bisectionAPD(S'_S, S'_S)$

Algo 3. BiNEXUS++ for using information of existing contour geometry

4.g End-to-End Incremental bouquet

I. Find new C_{max} post update and scale of selectivity change for each error-prone predicate
II. Check if any sub-ESS has any contour missing. If so, draw missing contours in that sub-ESS.
III. Compute Inflated MSO_g, If MSO_g is tolerable halt incremental compilation procedure
IV. Find Contour among non-static contours in existing ESS to re-draw to reduce MSG_g
V. Reconstruct the selected contour, using geometric information from past contour
VI. Detect and mark static contours
VII. Repeat Step II.

5 EXPERIMENTS

6 CONCLUSIONS

We have first reduced compilation overheads from what is done in past literature.

Given a proof on usage of Geometric progression to boundedly relax MSO_g, to remove need of high-resolution uniform distribution of selectivity values even for classical methods.

Later we have shown efficient methods to determining inflated MSO_g from using and old and extended ESS.

At last provide incremental bouquet maintenance algorithms & framework

7 FUTURE WORK

7.a Dimensionality Reduction

Since we have gone through conservative assumption that all query predicates are error prone. This will pose issue for $SchematicRed$ and $MaxSelRemoval$ provided in [6]. Since volume of data input to query plan from removed dimensions will also change upon update in database. Hence plan reuse from previous compilation may led to inflated MSO_g.

One basic improvement in $MaxSelRemoval$ can be to compute $MaxInflationFactor$ with some expected future update in all predicates and compute on corners of $E[Extended\ ESS]$ instead of $[\varepsilon, 1]^D$. Or to add a removed dimension later in future with $[1, 1+\Delta]$ selectivity interval, unlike an impactful predicate having selectivity interval of $[\varepsilon, 1+\Delta]$.

But in that case, ESS would not be a regular D-dimensional hypercube but have varying number of dimensions. When inflation factor degrades MSO_g, these ξ dimensions can be added back in some region of ESS. Making extended ESS to have $D+\xi$ dimensions.

No such improvement seems possible with $SchematicReduction$. While one thing to note is that $WeakDimRemoval$ is a technique applicable post compilation and can be incorporated in our framework for Incremental bouquet maintenance also.

7.a Selectivity Independence

While most work in literature has assumed predicate selectivity independence, it is not actually the case, and seldom holds in practice. Initial work to relax this assumption is done by [12].

While this assumption can be relaxed at contour level within SpillBound, as instead of assigning budget of CC_i for each predicate selectivity discovery independently. We can look if selectivity discovery for k predicates can explore in combined way with a budget of $k * CC_i$.

This may empirically reduce number of $Repeat\ Executions$ which constitute most in MSO_g proof of SpillBound algorithm, but will never deteriorate empirical performance.

We will leave this idea as future work to develop an algorithm to merge predicate selectivity discovery with combined budget, and if possible, to give a proof for improved MSO_g if selectivity dependence functions can be formulated a prior with some domain knowledge.
